**Abstract**—In this paper, we study stability property for a class of switched systems whose subsystems are *normal*. The subsystems can be continuous-time or discrete-time. When all continuous-time subsystems are Hurwitz stable and all discrete-time subsystems are Schur stable, we show that a common quadratic Lyapunov function exists for the subsystems and that the switched system is exponentially stable under arbitrary switching. When unstable subsystems are involved, we show that given a desired decay rate of the system, if the activation time ratio between unstable subsystems and stable ones is less than a certain value (calculated using the decay rate), then the switched system is exponentially stable with the desired decay rate.

### I. INTRODUCTION

In the last two decades, there has been increasing interest in stability analysis and controller design for switched systems; see the survey papers [1], [2], the recent book [3] and the references cited therein. The motivation for studying switched systems is from many aspects. It is known that many practical systems are inherently multimodal in the sense that several dynamical subsystems are required to describe their behavior which may depend on various environmental factors. Since these systems are essentially switched systems, powerful analysis or design results of switched systems are helpful dealing with real systems. Another important observation is that switching among a set of controllers for a specified system can be regarded as a switched system, and that switching has been used in adaptive control to assure stability in situations where stability can not be proved otherwise [4], [5], or to improve transient response of adaptive control systems [6]. Also, the methods of intelligent control design are based on the idea of switching among different controllers [7], [8]. Therefore, study on switched systems contributes greatly in switching controller and intelligent controller design.

When focusing on stability analysis of switched systems, there are three basic problems in stability and design of switched systems: (i) find conditions for stability/stabilizability under arbitrary switching; (ii) identify the limited but useful class of stabilizing switching laws; and (iii) construct a stabilizing switching law. There are many existing works on these problems in the case where the switched systems are composed of continuous-time subsystems. For Problem (i), Ref. [9] showed that when all subsystems are stable and commutative pairwise, the switched linear system is stable under arbitrary switching. Ref. [10] extended this result from the commutation condition to a Lie-algebraic condition. Ref. [11] showed that a class of switched symmetric systems are asymptotically stable under

arbitrary switching since a common Lyapunov function, in the form of  $V(x) = x^T x$ , exists for all the subsystems. Refs. [12]-[15] considered Problem (ii) using piecewise Lyapunov functions, and Refs. [16]-[17] considered Problem (ii) for switched systems with pairwise commutation or Lie-algebraic properties. Ref. [18] considered Problem (iii) by dividing the state space associated with appropriate switching depending on state, and Ref. [19] considered quadratic stabilization, which belongs to Problem (iii), for switched systems composed of a pair of unstable linear subsystems by using a linear stable combination of unstable subsystems. Ref. [20] considered quadratic stabilizability of switched linear systems with polytopic uncertainties, and Ref. [21] dealt with robust quadratic stabilization for switched LTI systems by using piecewise quadratic Lyapunov functions so that the synthesis problem can be formulated as a matrix inequality feasibility problem. Refs. [11], [22], [23], [24] extended the consideration to stability analysis problems for switched systems composed of discrete-time subsystems.

Motivated by the observation that all these papers deal with switched systems composed of only continuous-time subsystems or only discrete-time ones, the authors considered in a recent paper [25] the new type of switched systems which are composed of both continuous-time and discrete-time dynamical subsystems. It was pointed out there that it is very easy to find many applications involving such switched systems. For example, for a continuous-time plant, if we design a set of continuous-time controllers and a set of discrete-time controllers, and we choose an appropriate controller at every time instant, then the entire feedback system is in fact a switched system composed of both continuous-time and discrete-time subsystems. A cascaded system composed of a continuous-time plant, a set of discrete-time controller and switchings among the controllers is also a good example. Another example of a system of this kind is a continuous-time plant controlled either by a physically implemented regulator or by a digitally implemented one (and a switching rule between them). Ref. [25] gave some analysis and design results for several kinds of such switched system. For example, the case where commutation condition holds, and the case of switched symmetric systems. This paper aims to extend the results for switched symmetric systems in [25] to switched *normal* systems. For such switched systems, it is shown that when all continuous-time subsystems are Hurwitz stable and all discrete-time subsystems are Schur stable, a common quadratic Lyapunov function exists for the subsystems and that the switched system is exponentially stable under

arbitrary switching. Furthermore, when unstable subsystems are involved, we show that if the total activation time ratio between unstable subsystems and stable ones is less than a specified value (which is determined by the eigenvalues of the subsystems and the desired decay rate), then the switched system is exponentially stable with the desired decay rate. Three numerical examples are given to show the effectiveness of the results.

## II. PRELIMINARIES AND SYSTEM DESCRIPTION

In this section, we give some definitions and lemmas concerning normal systems, and then describe the switched system we consider in this paper.

*Definition 1:* A continuous-time system

$$\dot{x}(t) = Ax(t) \quad (1)$$

or a discrete-time system

$$x(k+1) = Ax(k) \quad (2)$$

is said to be *normal* if

$$A^T A = AA^T. \quad (3)$$

*Definition 2:* A real square matrix  $Q$  is said to be *orthogonal* if  $Q^T Q = I$ .

The following lemma characterizes a normal system matrix by orthogonally equalizing it to a block-diagonal matrix consisting of its eigenvalues (Theorem 4.10.69 in [26]).

*Lemma 1:* Suppose that  $A \in \mathbb{R}^{n \times n}$  is normal, its real eigenvalues are  $\lambda_1, \dots, \lambda_r$ , and its complex eigenvalues are  $a_1 \pm b_1 i, \dots, a_s \pm b_s i$ , where  $a_i$ 's and  $b_i$ 's are real,  $b_i \neq 0$ ,  $r + 2s = n$ . Then, there exists an orthogonal matrix  $Q$  such that

$$Q^T A Q = \text{diag}\{\lambda_1, \dots, \lambda_r, \Lambda_1, \dots, \Lambda_s\}, \quad (4)$$

where

$$\Lambda_i = \begin{bmatrix} a_i & b_i \\ -b_i & a_i \end{bmatrix}, \quad i = 1, \dots, s. \quad (5)$$

The following two lemmas play a key role in the next section.

*Lemma 2:* If the continuous-time system (1) is normal and Hurwitz stable, then

$$A^T + A < 0. \quad (6)$$

*Proof:* We obtain from (4) that

$$\begin{aligned} & Q^T (A^T + A) Q \\ &= \text{diag}\{2\lambda_1, \dots, 2\lambda_r, 2a_1, 2a_1, \dots, 2a_s, 2a_s\}. \end{aligned} \quad (7)$$

Since  $A$  is Hurwitz stable, we obtain that  $\lambda_i < 0 (1 \leq i \leq r)$  and  $a_j < 0 (1 \leq j \leq s)$  and thus  $Q^T (A^T + A) Q < 0$ , which is equivalent to  $A^T + A < 0$ . This completes the proof. ■

*Lemma 3:* If the discrete-time system (2) is normal and Schur stable, then

$$A^T A - I < 0. \quad (8)$$

*Proof:* We obtain from (4) that

$$\begin{aligned} & Q^T (A^T A) Q = \text{diag}\{\lambda_1^2, \dots, \lambda_r^2, \\ & a_1^2 + b_1^2, a_1^2 + b_1^2, \dots, a_s^2 + b_s^2, a_s^2 + b_s^2\}. \end{aligned} \quad (9)$$

Since  $A$  is Schur stable, we obtain  $|\lambda_i| < 1 (1 \leq i \leq r)$  and  $\sqrt{a_j^2 + b_j^2} < 1 (1 \leq j \leq s)$  and thus  $Q^T (A^T A) Q < I$ , which is equivalent to (8). ■

In this paper, we consider the switched system which is composed of a set of continuous-time subsystems

$$\dot{x}(t) = A_{ci} x(t), \quad i = 1, \dots, N_c \quad (10)$$

and a set of discrete-time subsystems

$$x(k+1) = A_{dj} x(k), \quad j = 1, \dots, N_d \quad (11)$$

where  $x(t), x(k) \in \mathbb{R}^n$  are the subsystem states,  $A_{ci}$ 's and  $A_{dj}$ 's are constant matrices of appropriate dimension. To discuss stability of the overall switched system, we assume for simplicity that the sampling periods of all the discrete-time subsystems are of the same value  $\tau$  (the discussion can be easily extended to the case where the discrete-time subsystems have different sampling periods). Since the states of the discrete-time subsystems can be viewed as piecewise constant vectors between sampling points, we can consider the value of the system states in continuous-time domain. For example, if subsystem  $A_{c1}$  is activated on  $[t_0, t_1]$  and then subsystem  $A_{d1}$  is activated for  $m$  steps and subsystem  $A_{c3}$  is activated from then to  $t_2$ , the time domain is divided into

$$[t_0, t_2] = [t_0, t_1] \cup [t_1, t_1 + m\tau] \cup [t_1 + m\tau, t_2] \quad (12)$$

and the system state takes the form of

$$x(t) = \begin{cases} e^{A_{c1}(t-t_0)} x(t_0), & t \in [t_0, t_1] \\ A_{d1}^k x(t_1), & t \in [t_1, t_1 + k\tau], 1 \leq k \leq m \\ e^{A_{c3}(t-t_1-m\tau)} x(t_1 + m\tau), & t \in [t_1 + m\tau, t_2] \end{cases} \quad (13)$$

Although  $x(t)$  is not continuous with respect to time  $t$  due to existence of discrete-time subsystems, the solution  $x(t)$  is uniquely defined at all time instants, and thus various stability properties can be discussed in continuous-time domain.

Throughout this paper, we make the following assumption.

*Assumption 1:* All the subsystems in (10) and (11) are *normal*, i.e.,

$$A_{ci}^T A_{ci} = A_{ci} A_{ci}^T, \quad A_{dj}^T A_{dj} = A_{dj} A_{dj}^T. \quad (14)$$

*Remark 1:* For switched symmetric systems, it is assumed in [24], [25] that  $A_{ci}^T = A_{ci}$  and/or  $A_{dj}^T = A_{dj}$ .

Obviously, Assumption 1 covers such symmetric systems. Furthermore, it covers the cases of  $A_*^T A_* = I$ ,  $A_*^T = -A_*$  and some other cases.

### III. ARBITRARY SWITCHING

In this section, we discuss the case where arbitrary switching is possible for the switched system composed of (10) and (11). Since arbitrary switching includes the case of dwelling on certain subsystem for all time, we make the following necessary assumption.

*Assumption 2:*  $A_{ci}$ 's are Hurwitz stable and  $A_{dj}$ 's are Schur stable.

It is known that Assumption 2 is not enough to guarantee stability under arbitrary switching. That is, a switched system composed of stable subsystems could be unstable if the switching is not done appropriately [1], [13]. However, when all subsystems are normal, we will show in the following that the switched system is exponentially stable under arbitrary switching.

*Theorem 1:* Under Assumptions 1 and 2, the switched system composed of (10) and (11) is exponentially stable under arbitrary switching.

*Proof:* Since all subsystems are normal, according to Lemma 1, we obtain

$$\begin{aligned} A_{ci}^T + A_{ci} &< 0, \quad i = 1, \dots, N_c; \\ A_{dj}^T A_{dj} - I &< 0, \quad j = 1, \dots, N_d. \end{aligned} \quad (15)$$

This implies that  $P = I$  is a common solution to the Lyapunov matrix inequalities

$$\begin{aligned} A_{ci}^T P + P A_{ci} &< 0, \quad i = 1, \dots, N_c; \\ A_{dj}^T P A_{dj} - P &< 0, \quad j = 1, \dots, N_d, \end{aligned} \quad (16)$$

and thus  $V(x) = x^T x$  is a common Lyapunov function for all the subsystems.

To show the exponential stability of the system, we need to find two positive scalars  $\alpha_c$  and  $\alpha_d < 1$  such that

$$A_{ci}^T + A_{ci} < -2\alpha_c I, \quad A_{dj}^T A_{dj} - \alpha_d^2 I < 0 \quad (17)$$

for all  $i$  and  $j$ . Then, in the period where a continuous-time subsystem is activated, we obtain  $\dot{V}(x(t)) < -2\alpha_c V(x(t))$ , and in the period where a discrete-time subsystem is activated,  $V(x(k+1)) < \alpha_d^2 V(x(k))$ .

For any time  $t > 0$  (when a discrete-time subsystem is active at  $t$ , we refer to  $t$  tacitly as the last sampling point since the state does not change until the next sampling point), we can always divide the time interval  $[0, t]$  as  $t = t_c + m\tau$  ( $m \geq 0$ ), where  $t_c$  is the total duration time on continuous-time subsystems and  $m\tau$  is the total duration time on discrete-time subsystems. It is not difficult to obtain that no matter what the activation order is,

$$V(x(t)) \leq e^{-2\alpha_c t_c} \alpha_d^{2m} V(x(0)) \quad (18)$$

and thus

$$|x(t)| \leq e^{-\alpha t} |x(0)| \quad (19)$$

where  $\alpha = \min\{\alpha_c, \frac{\ln(\alpha_d^{-1})}{\tau}\} > 0$ . This completes the proof. ■

*Remark 2:* It has been shown in the proof of Theorem 1 that when all subsystems are normal and (Hurwitz or Schur) stable,  $V(x) = x^T x$  is a common quadratic Lyapunov function for them.

*Example 1:* Consider the switched system composed of one continuous-time subsystem given by

$$A_{c1} = \begin{bmatrix} -0.6 & 0.8 \\ -0.8 & -0.6 \end{bmatrix} \quad (20)$$

and one discrete-time subsystem given by

$$A_{d1} = \begin{bmatrix} 0.45 & 0.6 \\ -0.6 & 0.45 \end{bmatrix}. \quad (21)$$

It is easy to confirm that both  $A_{c1}$  and  $A_{d1}$  are normal,  $A_{c1}$  is Hurwitz stable and  $A_{d1}$  is Schur stable. Suppose that the sampling period of subsystem  $A_{d1}$  is 0.1. Fig. 1 shows the convergence of the system trajectory where  $A_{c1}$  and  $A_{d1}$  are activated alternatively with respectively time period 1 and 5 steps (i.e., time period 0.5). The initial state is  $[100 \ 100]^T$ , and the mark “\*” in the upper part of Figure 1 describes the state change when the discrete-time subsystem  $A_{d1}$  is activated. The lower part of Fig. 1 connects all the sampling points of subsystem  $A_{d1}$  into a continuous trajectory.

Fig. 1. The system trajectory in Example 1

In the end of this section, we note that Theorem 1 is very useful in many switching control problems. Suppose that we have on hand an open-loop feedback system

$$\dot{x}(t) = Ax(t) + Bu(t) \quad (22)$$

where  $x(t)$  is the state,  $u(t)$  is the input,  $A, B$  are constant matrices of appropriate dimension. We also suppose that we can design a set of state feedback controllers  $u(t) = K_i x(t)$  ( $i = 1, \dots, N_m$ ), such that each  $A + BK_i$  is normal and Hurwitz stable. This is possible in many cases. For example, when

$$A = \begin{bmatrix} 1 & 3 \\ 2 & 4 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}, \quad (23)$$

it is easy to know that any  $K = \begin{bmatrix} k_1 & k_2 \\ k_3 & k_4 \end{bmatrix}$ , where  $k_1 < -1$ ,  $k_1 + k_4 = 3$  and  $k_3 - k_2 = 5$ , will make  $A + BK$  normal and Hurwitz stable.

If we can (or have to) choose one from the set of controllers at every time instant, the whole system is a switched system that is composed of Hurwitz stable subsystems. Since this is a special case of Theorem 1 (no discrete-time subsystems exist), we see that the system is exponentially stable no matter how we choose the controllers. This observation is very important in real applications when we want more flexibility to take other specification into consideration.

Obviously, the above discussion is also applicable to discrete-time feedback control systems, and to the case of output feedback switching problems. Furthermore, a more interesting problem may be feedback control systems which are composed of a continuous-time plant and both continuous-time and discrete-time controllers.

*Example 2:* For the system (22) with (23), we set

$$K_1 = \begin{bmatrix} -1.5 & 1 \\ 6 & 4.5 \end{bmatrix}, K_2 = \begin{bmatrix} -2 & -1 \\ 4 & 5 \end{bmatrix} \quad (24)$$

to obtain two closed-loop system matrix

$$A_{c1} = \begin{bmatrix} -0.5 & 4 \\ -4 & -0.5 \end{bmatrix}, A_{c2} = \begin{bmatrix} -1 & 2 \\ -2 & -1 \end{bmatrix} \quad (25)$$

which are normal and Hurwitz stable.

Now, we set the initial state as  $x_0 = [1 \ 1]^T$  and randomly generate 8 positive time periods among  $(0.01, 1)$  as  $T_1 = 0.95$ ,  $T_2 = 0.23$ ,  $T_3 = 0.61$ ,  $T_4 = 0.49$ ,  $T_5 = 0.89$ ,  $T_6 = 0.76$ ,  $T_7 = 0.46$ ,  $T_8 = 0.02$ . Then, we activate subsystem  $A_{c1}$  and  $A_{c2}$  alternatively with time period  $T_1, T_2, \dots, T_7, T_8$ . Fig. 2 shows the convergence of the system trajectory under such random activation periods.

Fig. 2. The system trajectory in Example 2

#### IV. TIME-CONTROLLED SWITCHING

In this section, assuming that some subsystems are not stable, we consider Problem (ii) for the switched system. We propose a class of time-controlled switching law which

specifies the total activation time ratio between unstable subsystems and stable ones.

For simplicity, we suppose that  $A_{c1}$  and  $A_{d1}$  are unstable, and all the other subsystems are stable. It will be seen later that other cases can be dealt with using the completely same manner.

According to Lemma 1, there exists an orthogonal matrix  $Q_{c1}$  such that

$$Q_{c1}^T (A_{c1}^T + A_{c1}) Q_{c1} = \text{diag}\{2\lambda_1^{c1}, \dots, 2\lambda_{r1}^{c1}, 2\eta_1^{c1}, 2\eta_1^{c1}, \dots, 2\eta_{s1}^{c1}, 2\eta_{s1}^{c1}\}, \quad (26)$$

where  $\lambda_1^{c1}, \dots, \lambda_{r1}^{c1}$  are  $A_{c1}$ 's real eigenvalues, and  $\eta_1^{c1}, \dots, \eta_{s1}^{c1}$  are the real parts of  $A_{c1}$ 's complex eigenvalues. Since  $A_{c1}$  is not Hurwitz stable, there is at least one nonnegative number among them. For design purpose, we define the scalar

$$\beta_c = \max\{\lambda_1^{c1}, \dots, \lambda_{r1}^{c1}, \eta_1^{c1}, \dots, \eta_{s1}^{c1}\}. \quad (27)$$

It is then easy to see that  $\beta_c \geq 0$  and

$$A_{c1}^T + A_{c1} \leq 2\beta_c I. \quad (28)$$

Similarly, for Schur unstable  $A_{d1}$ , there exists an orthogonal matrix  $Q_{d1}$  such that

$$Q_{d1}^T (A_{d1}^T A_{d1}) Q_{d1} = \text{diag}\{(\lambda_1^{d1})^2, \dots, (\lambda_{u1}^{d1})^2, (\eta_1^{d1})^2, (\eta_1^{d1})^2, \dots, (\eta_{v1}^{d1})^2, (\eta_{v1}^{d1})^2\}, \quad (29)$$

where  $\lambda_1^{d1}, \dots, \lambda_{u1}^{d1}$  are  $A_{d1}$ 's real eigenvalues, and  $\eta_1^{d1}, \dots, \eta_{v1}^{d1}$  are the absolute values of  $A_{d1}$ 's complex eigenvalues. Since  $A_{d1}$  is not Schur stable, there is at least one number among them which is not less than 1. If we define

$$\beta_d = \max\{\lambda_1^{d1}, \dots, \lambda_{u1}^{d1}, \eta_1^{d1}, \dots, \eta_{v1}^{d1}\}, \quad (30)$$

then  $\beta_d \geq 1$  and

$$A_{d1}^T A_{d1} \leq \beta_d^2 I. \quad (31)$$

From now on, we use the Lyapunov function candidate  $V(x) = x^T x$  to discuss the system's stability. According to (28), when subsystem  $A_{c1}$  is activated, we obtain  $\dot{V}(x(t)) \leq 2\beta_c V(x(t))$ . According to (31), when subsystem  $A_{d1}$  is activated, we obtain  $V(x(k+1)) \leq \beta_d^2 V(x(k))$ . Except these two subsystems, we assume that (17) is satisfied for  $i \neq 1$  and  $j \neq 1$ .

Now, for any time  $t > 0$  (when a discrete-time subsystem is active at  $t$ , we refer to  $t$  tacitly as the last sampling point since the state does not change until the next sampling point), we assume that the time interval  $[0, t]$  is divided as  $t = t_{c1} + t_{cs} + m_{d1}\tau + m_{ds}\tau$ , where  $t_{c1}$  is the total activation time of  $A_{c1}$ ,  $t_{cs}$  is the total activation time of other continuous-time subsystems,  $m_{d1}\tau$  is the total activation time of  $A_{d1}$ , and  $m_{ds}\tau$  is total activation time of other discrete-time subsystems. Then, it is easy to obtain

$$V(x(t)) \leq e^{2\beta_c t_{c1}} e^{-2\alpha_c t_{cs}} \beta_d^{2m_{d1}} \alpha_d^{2m_{ds}} V(x(0)). \quad (32)$$

Using  $\beta = \max\{\beta_c, \frac{\ln(\beta_d)}{\tau}\}$  in the above leads to

$$V(x(t)) \leq e^{2\beta(t_{c1}+m_{d1}\tau)} e^{-2\alpha(t_{cs}+m_{ds}\tau)} V(x(0)), \quad (33)$$

where  $\alpha$  is the same as defined in the proof of Theorem 1. Noting that  $T_u = t_{c1} + m_{d1}\tau$  is the total activation time of unstable subsystems, and  $T_s = t_{cs} + m_{ds}\tau$  is total activation time of stable subsystems, we consider the following time-controlled switching law:

*Time-controlled switching law:* Let  $T_u$  and  $T_s$  be the total activation time of all unstable subsystems and stable ones, respectively, and let  $\alpha_* < \alpha$  be desired decay rate of the overall system. Keep the ratio between  $T_u$  and  $T_s$  satisfying

$$\frac{T_u}{T_s} \leq \frac{\alpha - \alpha_*}{\beta + \alpha_*}. \quad (34)$$

In fact, we obtain from (34) that

$$(\beta + \alpha_*)T_u \leq (\alpha - \alpha_*)T_s. \quad (35)$$

Then, combined with (33), we obtain

$$|x(t)| \leq e^{-\alpha_* t} |x(0)|. \quad (36)$$

We summarize the above discussion in the following theorem.

*Theorem 2:* Under Assumption 1 and the time-controlled switching law (34), the switched system is exponentially stable with decay rate  $\alpha_*$ . ■

*Remark 3:* Compared with the existing result in [14], where switched systems including both stable and unstable subsystems were also dealt with, there is no requirement on *average dwell time* concerning any single subsystem. It is easy to see that the time-controlled switching law (34) is not involved with the number of switchings, which usually appears in the average dwell time scheme. The reason is that for the switched normal systems under consideration, we have shown that  $V(x) = x^T x$  together with the time-controlled switching law is in fact a kind of *common quadratic Lyapunov-like function* [27] in the present case. We used “Lyapunov-like” here since it is not a Lyapunov function in the usual sense, especially for unstable subsystems, yet it is an auxiliary scalar-valued function involved with a Direct Method and exponential stability of the entire system is guaranteed.

*Example 3:* Consider the switched system composed of one continuous-time subsystem given by

$$A_{c1} = \begin{bmatrix} 0.6 & 0.8 \\ -0.8 & 0.6 \end{bmatrix} \quad (37)$$

and one discrete-time subsystem given by

$$A_{d1} = \begin{bmatrix} 0.3 & 0.4 \\ -0.4 & 0.3 \end{bmatrix}. \quad (38)$$

It is easy to confirm that both  $A_{c1}$  and  $A_{d1}$  are normal,  $A_{c1}$  is Hurwitz unstable and  $A_{d1}$  is Schur stable. Then, it is easy to compute

$$\beta_c = 0.6, \quad \alpha_d = 0.5. \quad (39)$$

Fig. 3. The system trajectory in Example 3

If we choose  $\tau = 1$  as the sampling period of  $A_{d1}$ , then

$$\alpha = \frac{\ln(\alpha_d^{-1})}{\tau} = 0.69, \quad \beta = \beta_c = 0.6. \quad (40)$$

According to Theorem 2, if the desired decay rate is  $\alpha_* = 0.4$ , then the time ratio of  $A_{c1}$  and  $A_{d1}$  should satisfy

$$\frac{T_u}{T_s} \leq \frac{\alpha - \alpha_*}{\beta + \alpha_*} = \frac{0.69 - 0.4}{0.6 + 0.4} = 0.29. \quad (41)$$

In order to meet this requirement, we activate  $A_{c1}$  and  $A_{d1}$  alternatively with respectively time period 2.9 and 10 steps. Fig. 3 shows that the system trajectory still converges to zero very quickly in this case (with the same initial state  $[100 \ 100]^T$ ).

*Remark 4:* It is finally noted that the discussion and result in this section can be applied to controller failure time analysis of feedback control systems when the original system matrix is normal and the feedback is designed so that the closed-loop system is also normal. In this case, the overall system can be viewed as a switched system composed of the original unstable system and the stable closed-loop system. For detailed discussion, refer to [28].

## V. CONCLUDING REMARKS

In this paper, we have studied stability property for a class of switched systems which are composed of both continuous-time and discrete-time LTI normal subsystems. We have shown that when all continuous-time subsystems are Hurwitz stable and all discrete-time subsystems are Schur stable, a common quadratic Lyapunov function  $V(x) = x^T x$  exists for the subsystems and that the switched system is exponentially stable under arbitrary switching. When unstable subsystems are involved, we have shown that if the activation time ratio between unstable subsystems and stable ones is less than a specified value, then the switched system is guaranteed to be exponentially stable with a desired decay rate.

Compared with the three basic problems mentioned in the introduction, we note that the results in this paper points

to Problem (i) and part of Problem (ii). Presently, we are trying to take advantage of the structure of switched normal systems in dealing with the stabilization problem (Problem (iii)). Furthermore, although we still have not proved it, we are conjecturing that if the expanded matrix  $\begin{bmatrix} A & B \\ C & D \end{bmatrix}$  is normal, then the stable system with input and output

$$\dot{x} = Ax + Bw, \quad z = Cx + Dw \quad (42)$$

or its discrete-time counterpart will have a quadratic Lyapunov function  $V(x) = x^T x$  in  $\mathcal{L}_2$  sense. If this is true, then we can prove that the switched system composed of normal stable subsystems with the same  $\mathcal{L}_2$  gain  $\gamma$ , will be stable and keep the  $\mathcal{L}_2$  gain  $\gamma$  under arbitrary switching. This problem is also in our future research.
